In this study, we aimed to analyze our surgically treated patients with palpable solitary solid nodule of the thyroid gland exclusively from the endemic region. Our series have a mean age of 48 (21-75) years, and thirty-two (73%;32/44) patients were female.

**Blood chemistry:** Thyroid function was established biochemically by measurement of serum concentrations of thyroid stimulating hormone (TSH), free triiodothyronine (FT3), free thyroxin (FT4). Ultrasound: The thyroid was examined by high resolution ultrasound. This examination has evaluated the size, echo-structure (solid or cystic), shape and number of nodule(s), and extranodular thyroid tissue. The presence of single (solitary) solid nodule in one lobe of the gland, and relatively homogeneous extranodular tissue has been reported in all our 44 cases.

**Pathologic anatomy:** Fine needle aspiration cytology (FNAC) was performed on all palpable nodules of 44 patients either directly or by ultrasound guide. Postoperatively, the histopathological examination of excised thyroid tissue has reported the final diagnosis. The results of physical examination, blood chemistry, ultrasound have indicated surgical management of our patients with solitary solid nodule of the thyroid. Our cases of hyperthyroidism were medically controlled in an endemic goiter area due to low iodine intake.

**Methods**

In a period of 6 years (Between 2009 and 2015), We determined 44 (17.4%) patients who have palpable solitary solid nodule of the thyroid gland exclusively from the endemic region.

**Demography:** Our series have a mean age of 48 (21-75) years, and thirty-two (73%;32/44) patients were female.

**Introduction**

Hypertrophy of the thyroid and nodular formation in the gland is a common occurrence in endemic region. It has been reported that exogenous iodine intake affects the pathogenesis of thyroid nodules. [1],[2], [3],[4],[5],[6],[7] Palpable thyroid nodule(s) of which great majority are asymptomatic occurs in 5% of the population. [8],[9],[10] Approximately 5% of all palpable thyroid nodules have been reported as malignant.[10] Some predisposing pathological features increase clinical importance of thyroid nodule(s). A significant feature is nodule size . A palpable thyroid nodule at physical examination, especially greater than 2 cm of diameter carries a considerable risk of annoying disorder. [11],[12],[13] Another main feature is structural (solid and cystic) nature of the nodule. Especially, management of a larger solid nodule merits a distinct importance.[11],[12],[14],[15] A third feature is functional status of the nodule. The activity of a nodule may be established by chemical hormonal analysis and nuclear imaging method. A hyperactive or hypoactive nodule significantly influences clinical outcome of a patient. [9],[10] A forth important characteristic of the nodule is its solitary feature. A solitary nodule carries greater clinical importance than multinodular formation.[14] Based on clinical, chemical and image characteristics, the thyroid nodule which possess all these four pathological features (large size, solitary, solid, hypo or hyperactive) is generally treated by surgical intervention.

In this study, we aimed to analyze our surgically treated patients with palpable solitary solid nodule of the thyroid gland which possess all these four pathological features (large size, solitary, solid, hypo or hyperactive) is generally treated by surgical intervention.

**Statistical analysis:** Student t test and Fisher’s exact test.

**Results:** Twenty (45%;20/44) patients with hot (autonomous) nodule have received the diagnosis of toxic adenoma. Twenty four patients had solitary solid and cold nodule. Total thyroidectomy was performed on two patients with papillary cancer (PTC) diagnosed by FNAC from cold nodules. Forty two patients have been treated with total excision of the lobe including hyper or hypoactive solitary solid nodule. Pathological examination has reported two more cases of PTC and one case of insular cancer arising from cold nodules. Completion thyroidectomy was performed on these 3 patients.

**Conclusions:** Solitary solid and large nodule is a common indication for thyroid surgery in endemic goiter area. High incidence of hyperthyroidism due to single autonomous nodule, and high rate of malignant change (mainly papillary cancer) in solitary hypoactive nodule arises from this series in endemic thyroid enlargement.

**ABSTRACT**

Context: Endemic area and iodine supplementation may affect the pathogenesis of the nodule which commonly occurs in endemic thyroid enlargement due to iodine deficiency.

Aims: To establish pathological changes in solitary solid and larger nodule of the thyroid in endemic area.

Setting and Design: Retrospective study in Surgical Department of Kurnool Medical college and Government general Hospital, Kurnool.

Methods and Material: We determined 44 surgically treated patients with solitary solid nodule only in endemic goiter area in which the population routinely receives iodinated salt. The thyroid nodule was preoperatively evaluated with blood chemistry, Ultrasound and FNAC. The results of preoperative evaluation, surgical interventions, and histopathological examination were analyzed.

**Statistical analysis:** Student t test and Fisher’s exact test.

**Results:** Twenty (45%;20/44) patients with hot (autonomous) nodule have received the diagnosis of toxic adenoma. Twenty four patients had solitary solid and cold nodule. Total thyroidectomy was performed on two patients with papillary cancer (PTC) diagnosed by FNAC from cold nodules. Forty two patients have been treated with total excision of the lobe including hyper or hypoactive solitary solid nodule. with antithyroid drugs before the operation. We analyzed demographic features of patients, results of preoperative evaluation, surgical methods, final pathological diagnosis and postoperative outcome of patients.

Statistical analysis: Statistical analysis was made using student t test and Fisher’s exact test, and p<0.05 was accepted as significant.

Results
Preoperative evaluation: We determined 32 (73%) female and 12 male patients with solitary solid nodule of the thyroid who were surgically treated after preoperative evaluation. Blood chemistry has showed hyperthyroidism in 20 (45%) patients. Ultrasonography has diagnosed solitary, solid nodule in all 44 patients.

Diagnosis: Clinical and chemical hyperthyroidism has leaded the diagnosis of toxic adenoma in 20 patients. The indication for surgery was toxic adenoma in 20, inactive solid nodule in 22 and PTC diagnosed by FNAC in 2 patients.

Surgery: Total thyroidectomy was performed on 2 patients with preoperative diagnosis of PTC, and unilateral total lobectomy and excision of the isthmus on the remaining 42 patients.

Pathology: In addition of 2 PTC cases, malignancy was reported by postoperative histopathologic examination in 3 patients with non-diagnostic FNAC. Therefore, the rate of cancer was 21% (5/24) in patients with solitary solid hypoactive (cold) nodule.

Secondary surgery: A secondary operation for total excision of the remaining contralateral lobe (completion thyroidectomy) was performed on three patients in whom pathologic examination has established the diagnosis of malignancy in previously excised lobe. Functional neck dissection was added to completion thyroidectomy in our patient who has had pathological diagnosis of poorly differentiated insular carcinoma. Fortunately, this patient did not have involvement contralateral lobe, extrathyroidal extension, lymphatic and distant metastasis.

Early postoperative management: The recovery was uneventful in all patients. Five malignant cases treated with total thyroidectomy have received a suppressive dose of L-thyroxin. Postoperatively, serum levels of TSH were in normal range in 39 patients treated with unilateral total lobectomy.

Discussion
Alimentary iodine intake by iodinated salts has been programmed in the last 15 years for resolving the iodine deficiency in our region. On the other hand, exogenous iodine supplementation affects the presentation of the present nodule. Autonomy of some nodules leads to thyrotoxicosis in some middle and advanced aged patients with nodular goiter. Type of malignant progression has also been affected by exogenous iodine intake. [1],[2],[3],[4],[5],[6],[7] It has been reported that solitary, solid and large sized nodule possesses a different clinical and pathological significance for surgical evaluation. In this study we analyzed our surgically treated patients with solitary solid and larger nodule which has occurred in endemic thyroid enlargement. High resolution ultrasound is the best imaging modal-
definitive conclusion, based on our findings we have concluded that solitary solid and large nodule has a considerable rate among surgically treated patients with nodular goiter in endemic area. Ultrasound objectively defines cellular architecture of the nodule. High incidence of hyperthyroidism due to single autonomous nodule is a common finding in endemic goiter region. Solitary hypoactive and larger nodule possess high rate of malignant change. High rate of hyperthyroidism and well differentiated (papillary) thyroid cancer in larger solid nodule which occurs in endemic enlargement of the thyroid reveals potential influence of alimentary iodine supplementation on the pathogenesis of the nodule.
