ABSTRACT Antin	nicrobial resistance is a growing threat worldwide. Increasing resistance to third generation cephalosporins has		

become a cause for more concern among Enterobacteriaceae. The prevalence of extended spectrum -lactamases (ESBLs) and metallobetalactamases (MBL) among members of Enterobacteriaceae constitutes a serious threat to current situation of -lactam therapy leading to treatment failure. 100 Enterobacteriaceae isolated from various clinical samples were included in the study. ESBL was detected by phenotypic confirmatory disc diffusion test (PCDDT) using ceftazidime alone and in combination with clavulanic acid. MBL detection was done by Imipenem EDTA combined disc diffusion test. Out of 100 Enterobacteriaceae isolates, 47(47%) were ESBL producers and 29 (29%) were MBL producers. None of the isolates showed the coexistence of ESBL and MBL in the same isolate. ESBL and MBL production was observed in *E.coli, Klebsiella* spp., Acinetobacter spp. and *Citrobacter* spp. isolated from various clinical samples. The study underlines problem of ESBL and MBL mediated resistance, which has created a therapeutic challenge for the clinicians and microbiologists. Simple disk method can be routinely employed to detect these common resistance mechanisms which will reduce the mortality and also spread of such resistant strains.

KEYWORDS:

INTRODUCTION

Resistant bacteria are emerging worldwide as a threat to the favorable outcome of common infections in community and hospital settings. Hospital acquired infections are most commonly caused by Gramnegative bacilli, particularly by members of Enterobacteriaceae family. The rapid and irrepressible increase in antimicrobial resistance of pathogenic bacteria is widely accepted as a major problem that has been observed over the lactams (mainly extended-spectrum cephalosporins and carbapenems) and fluoroquinolones constitute the main therapeutic choices to treat infections caused by these microorganisms (Coque et al., 2008). The enzymes, namely ßlactamases, which are responsible for the wide-spread of ß-lactam resistance. These ß -lactamases hydrolyse the amide bond of the fourmembers characteristic ß-lactam ring, thus rendering the antimicrobial ineffective (Prashant Durwas Peshattiwar and Basavaraj Virupaksappa Peerapur, 2011). The introduction of the third generation cephalosporins was very much helpful in fighting against the beta-lactamases in clinical practice (Rajesh Kondian Rangachari et al., 2010). Resistance to third generation oxyimino-cephalosporins is mediated by extended spectrum beta-lactamase enzymes (Sridhar Rao et al., 2008). ESBL producing isolates, in addition to being resistant to ß-lactam antibiotics, often exhibit resistance to other classes of drugs such as aminoglycosides, cotrimoxazole, tetracycline and fluoroquinolones (Dinesh et al., 2011). ESBLs are often located on plasmids that are transferable from strain to strain and between bacterial species (Mark E. Rupp and Paul D. Fey, 2003).

Carbapenems represented a great advance for the treatment of serious bacterial infections caused by beta-lactam resistant bacteria (Hodiwala et al., 2013). Due to their broad spectrum of activity and stability to hydrolysis by most ß lactamase, the carbapenems have been the drugs of choice for treatment of infections caused by penicillin or cephalosporin resistant gram negative bacilli (Nirav P. Pandya et al., 2011). But extensive and sometime unnecessary use of the carbapenems, poor sanitation and large population has facilitated the emergence of carbapenem resistant bacteria (Debasrita Chakraborty et al., 2010). Resistance to carbapenem is predominantly mediated by metallo-beta- lactamases, a class B type of beta lactamases that recognize bivalent metal ions (Anil Rajput et al., 2012). The multidrug resistant isolates that are present in the ICU and in the hospital environment pose not only therapeutic problems but also serious concerns for infection control management (Varun Goel et al., 2013). Early detection of MBL and ESBL producing organisms is crucial to establish appropriate antimicrobial therapy and to prevent their interhospital and intra-hospital dissemination (Nirav P. Pandya et al., 2011). So the present study were undertaken to detect ESBL and MBL in clinical isolates of Enterobacteriaceae.

MATERIALS AND METHODS

A total of 100 clinical isolates of Enterobacteriaceae, which were isolated from various clinical samples (Blood, urine, sputum, exudates, ear discharge, ET secretion, fluid) were identified by standard procedures (Collee *et al.*, 2007). The susceptibility of isolates to antibiotics was determined by Kirby- Bauer disc diffusion method using Clinical and Laboratory Standard Institute (CLSI) guidelines (2019). Antibiotics included were Aztreonam (30 μ g), Cefipime (30 μ g), Cefotaxime (30 μ g), Cefoxitin (30 μ g), Ceftazidime (30 μ g), Meropenem (10 μ g), Tobramycin (10 μ g), Amikacin (30 μ g), Pipracillin (100 μ g), Cefuroxime (30 μ g), Ciprofloxacin (5 μ g), Ceftriaxone (30 μ g) . Isolates resistant to the third generation cephalosporins were tested for ESBL production and isolates showing resistance to Imipenem were tested for MBL production.

Detection of MBL: These were performed by Imipenem EDTA combined disc test. Two (10 mcg) Imipenem discs were placed on a plate inoculated with the test organism on Mueller Hinton agar, and 10µl of 0.5 M EDTA solution was added to one disc. A zone diameter difference between the Imipenem and Imipenem + EDTA of \geq 7 mm was interpreted as a positive result for MBL production.

Detection of ESBL: These were performed by phenotypic confirmatory test as per the recommendations of CLSI. The ceftazidime (30 g) discs alone and in combination with clavulanic acid (ceftazidime + clavulanic acid, 30/10 g discs) were used. An increase of 5mm in zone of inhibition of the combination discs in comparison to the ceftazidime disc alone was considered to be ESBL producer.

RESULT AND DISCUSSION

Out of 100 Enterobacteriaceae isolates, 47 were ESBL producers and 29 MBL producers. *E. coli* showed maximum ESBL production (61%) followed by Klebsiella spp (48%). Maximum MBL production was seen in *Klebsiella* spp. (40%) and *E.Coli* (34%). Majority of ESBL and MBL producers were from blood followed by urine, Fluid and ET secretion.

Recently, the worldwide emergence of multi-drug resistant bacterial strains is a growing concern which are usually found in those hospitals where frequent use of antibiotic and the patients are in critical condition (Shahanara Begum *et al.*, 2013). Broad resistance spectrum is a cause for concern and necessitates the restricted use of extended-spectrum cephalosporins, and a trial of other suitable alternatives drugs (Amita Jain *et al.*, 2003). Therapeutic options for the infections

which are caused by the ESBL producers have also become increasingly limited (Metri Basavaraj et al., 2011). A study has found ciprofloxacin to be highly effective in treating multiresistant Gramnegative infections (Amita Jain et al., 2003). Recent studies on ESBL production among the members of Enterobacteriaceae which were isolated from clinical specimens, showed an increase in the occurrence of ESBL producers (Umadevi et al., 2011).

Table.1 ESBL and	d MBL producers amor	ng different isolates

Organism		ESBL producers	MBL producers
	N=100	No. (%)	No. (%)
E. coli	44	27 (61%)	15 (34%)
Klebsiella spp.	27	13 (48%)	11 (40%)
Pseudomonas spp.	05	01 (20%)	00
Citrobacter spp.	04	01 (25%)	01 (25%)
Acinetobacter spp.	17	04 (23.5%)	02 (11.7%)
Proteus spp	03	01 (33.3%)	00
Total	100	47 (47%)	29 (29%)

Table.2 Distribution of ESBL and MBL producers in various clinical specimens

Sample	No. of isolates	ESBL producers No.	MBL producers
	n=100	(%)	No. (%)
Urine	22	11 (50%)	05 (22.7%)
Pus	36	16 (44.4%)	10 (27.7%)
Sputum	08	03 (37.5%)	01 (12.5%)
Et secretion	28	13 (46.4%)	12 (42%)
Fluid	02	01 (50%)	00
Blood	04	03 (75%)	01(25%)
Total	100	47 (47%)	29 (29%)

In our study of the 100 Enterobacteriaceae isolates, 47 were ESBL producers. ESBLs were predominantly present among E. coli 27 (61%) compared to Klebsiella spp. 13 (48%), Proteus spp. 01(33.3%) and Citrobacter spp. 1(25%). Majority of ESBL producers were from blood (75%). Our findings are similar to that of Nachimuthu Ramesh et al., (2008) and Kumar et al., (2006) who reported a high prevalence of ESBLs among E. coli.

Correct identification of ESBL positive Enterobacteriaceae in due time is mandatory not only for optimal patient management but also for immediate institution of appropriate infection control measures to prevent the spread of these organisms (Irith Wiegand et al., 2007). Early detection will definitely help in controlling hospital infections which are caused by this group of organisms (Umadevi et al., 2011). The double disc synergy test (DDST) lacks sensitivity because of the problem of optimal disc space and the correct storage of the clavulanic acid containing discs. Assuming that a laboratory is currently testing the sensitivity for ceftazidime by using the disc diffusion test and it required only one disc to be added to the sensitivity plate by phenotypic confirmatory disc diffusion test and would screen all gram negative bacteria in the diagnostic laboratory for ESBL production. This method is technically simple and inexpensive (Gaurav Dalela, 2012). The only ß -lactam active against co- AmpC and ESBL producers are carbapenems; however, recently resistance to carbapenems has been increasing, which is mostly due to the production of metallo- β- lactamases (Supriya Upadhyay et al., 2010).

Metallo- ß -lactamases (MBLs) are enzymes belonging to Ambler s class B that can hydrolyze a wide variety of β -lactams, including penicillins, cephems, and carbapenems except aztreonam (Hisaaki Nishio et al., 2004; Krishna, 2010). Although, PCR method is simple to use in detecting MBL producing isolates, it has become more difficult with the increased number and types of MBL (Uma Chaudhary et al., 2008). Combined disc test is simple to perform and highly sensitive in differentiating MBL-producing isolates (Irene Galani et al., 2008).

Thus, implementation of simple method using imipenem- EDTA disk for MBL detection is quick, specific, sensitive and reproducible (Uma Chaudhary et al., 2008). Our study showed MBL production in 29 isolates with maximum production in Klebsiella spp. (40%), E.coli (34%) and Citrobacter spp (25%) which is consistent with studies by Varun goel et al., (2013) and Pandya et al., (2011). Production of MBL has tremendous therapeutic consequences since these organisms also carry multidrug resistance genes and the only viable option remains the potentially toxic polymyxin B and colistin (Veenu gupta et al., 2013).

The early detection of beta lactamase producing isolates would be

important for the reduction of mortality rates for patients and also to avoid the intra hospital dissemination of such strains. Simple phenotypic screening tests are proved to be rapid and convenient for their detection in the clinical laboratory. To overcome the problem of emergence and the spread of multidrug resistant organisms, a combined interaction and cooperation between the microbiologists, clinicians and the infection control team is needed.
