Neurocysticercosis is the commonest central nervous system parasitic disease worldwide but cysticercal hypointense on T1-weighted images [Fig. 3a] with focal restricted diffusion. The lesions were appearing relatively signal intensity on the axial ADC map Fig. 2c-d], reflecting diffusion weighed images [Fig. 2a-b] were showing hyper-inversion recovery (FLAIR) sequence [Fig. 1e-h]. The lesions in T2-weighted MR images involving the deep white brain revealed multiple fluffy nodular hyperintense signals in T2-weighted MR images involving the deep white matter of bilateral frontal lobes and left parietal lobe [Fig. 3c]. Similar findings were noted in the fluid attenuated inversion recovery radiological features of cysticercal meningoencephalitis in a 6 year old boy, who was admitted to our hospital with history of fever and headache since last three months and recently developed right sided weakness. Cerebrospinal fluid analysis of the patient showed eosinophilia with multiple bilateral cerebral hemispheric lesions at magnetic resonance imaging. Enzyme immune assay demonstrated IgG cysticercosis antibody in serum. Improvement in clinical and laboratory results was achieved using albendazole and corticosteroids.

Laboratory investigations gave the following results: Hemoglobin 8.4 g/dl (normal range: 11 - 15 g/dl); total white blood cell count 6,570 cells/mm\(^3\) (normal range: 4000 – 10,000 cells/mm\(^3\)); differential count – neutrophils: 36\%; lymphocytes: 59\%; monocytes: 3\%; eosinophils: 2\%; platelets adequate; and erythrocyte sedimentation rate 126 mm/1st hour (normal range: 0 – 20 mm). Pleural fluid ADA (0.9 U/L) noted within normal range. Serum electrolytes, blood sugar 13 mg/dl (normal range 40 – 80 mg/dl). Gram stain and Ziel-Habermann stain did not reveal any organism. CSF culture was negative.

CSF analysis showed the following results: Total cell count 520 cells/μL (normal range 0–5 cells/μL); differential count – eosinophils: 75\%, lymphocytes: 15\%, neutrophils: 10\%; RBC 4+; protein 100 mg/dl (normal range 15 – 60 mg/dl); and glucose 13 mg/dl (normal range 40 – 80 mg/dl). Gram stain and Ziehl–Neelsen stain did not reveal any organism. CSF culture was negative.

Computed tomography scan of his brain was normal. MRI brain revealed multiple fluffy nodular hyperintense signals in T2-weighted MR images involving the deep white matter of bilateral frontal lobes and left parietal lobe [Fig. 1a-b], left centrum semiovale [Fig. 1c] and left pons [Fig. 1d]. Similar findings were noted in the fluid attenuated inversion recovery (FLAIR) sequence [Fig. 1e-h]. The lesions were more distinct on the diffusion imaging. The diffusion weighed images [Fig. 2a-b] were showing hyperintense deep white-matter lesions with corresponding low signal intensity on the axial ADC map Fig. 2c-d], reflecting restricted diffusion. The lesions were appearing relatively hypointense on T1-weighted images [Fig. 3a] with focal enhancement of the genu of corpus callosum [Fig.3b]. Subtle enhancement of the basal meninges was also noted [Fig. 3c].

Serum analysis - Fluoroimmunoassay was non - reactive for IgG & IgM Toxoplasma antibody. Enzyme immune assay (EIA) demonstrated high titer of IgG cysticercosis antibody in serum [Index 1.63 U with Bio. Reference Interval < 0.9 U].

The patient received oral albendazole and prednisolone for 2 weeks and was discharged after gradual improvement of symptoms as well as laboratory results.

The diagnosis of eosinophilic meningoencephalitis is based on clinical manifestations and microscopic identification of eosinophils present in cerebrospinal fluid (CSF). CSF eosinophilia is defined by counts higher than 10 eosinophils per ml or 10% of the total CSF leukocyte count. Although any tissue-migrating helminths can cause eosinophilic meningitis, the most common cause is human infection with Taenia solium, the pork tapeworm. The intermediate stage of T. solium is infectious for humans and preferentially invades the CNS, causes neurocysticercosis. Humans acquire the intermediate stage by ingestion of food or water contaminated with the eggs of T. solium [1].

In most of the developing countries, NCC comprises 10% of acute neurologic cases. Epilepsy is the usual presentation, other known manifestations include raised intracranial pressure, meningoencephalitis, focal neurological deficit and psychiatric symptoms [2]. The entity of eosinophilic meningoencephalitis as part of the spectrum of NCC is observed to be rare in comparison to other symptoms. A very few cases have been reported in the literature [3-4].

The diagnosis of eosinophilic meningoencephalitis is based on clinical manifestations and microscopic identification of eosinophils present in cerebrospinal fluid (CSF). CSF eosinophilia is defined by counts higher than 10 eosinophils per ml or 10% of the total CSF leukocyte count. Although any tissue-migrating helminths can cause eosinophilic meningitis, the most common cause is human infection with Angiostrongylus cantonensis. Other parasites that can cause eosinophilic meningitis include Gnathostoma spinigerum, Baylisascaris procyonis, Toxocara canis, Toxoplasma gondii, and T. solium. Neurocysticercosis is most frequent cause of eosinophilia in CSF [3,5], although cysticercal meningitis is uncommon in India [3].

ASSOCIATE PROFESSOR, DEPARTMENT OF RADIOLOGY, RIMS, IMPHAL
Radiologic abnormalities in eosinophilic meningoencephalitis have been described rarely, though MR findings may aid pre-mortem diagnosis and help predict the prognosis. A few MR findings in previously reported cases of eosinophilic meningoencephalitis include hyperintense signals throughout the cerebral cortex on T2-weighted images. Abnormal enhancing subcortical, periaqueductal and basal cisternal lesions probably related to disruption of the blood-brain barrier caused by the eosinophilic inflammatory reactions, are also described [6]. The brain computed tomographic (CT) scan can be normal or can reveal cerebral edema, ventricular dilatation, enhancing ring or disc lesions, resembling tuberculomas [7].

Cysticercal meningoencephalitis is caused by infiltration of the meninges and the parenchyma of the brain by a large number of parasites, and inflammation in the surrounding tissue is responsible for meningitis and encephalitis [3].

Around 60% cysticercal meningoencephalitis cases have been reported to have associated brain parenchymal lesions [3]. Imaging features of parenchymal neurocysticercosis varies with stages. Vesicular stage exhibits cyst with “dot” (scolex), without significant edema or enhancement. Colloidal vesicular stage appears as ring enhancing lesion with striking edema. In granular nodular stage faint rim enhancement can be seen. A small calcified nodule without surrounding edema or enhancement is seen in nodular calcified stage [8].

In a previous case report of cysticercal meningitis, contrast enhanced CT study of the brain showed single hypodense lesion with an eccentric enhancing mural nodule suggestive of granulomatous parenchymal lesion [3]. In another case report by Amir M. et al. MR study of brain revealed multiple intraparenchymal and intraventricular cysticercal lesions (peripheral rim enhancing lesions) with hydrocephalus [9]. Our MR findings revealed T2 hyperintense signal involving deep white matter. These are nonspecific findings that may indicate small vessel ischemic changes, demyelination or gliosis. Focal enhancement of genu of the corpus callosum was noted, without any specific imaging feature of granulomatous parenchymal lesion.

The CSF findings in cysticercal meningitis consist of pleocytosis (usually lymphocytic but frequently polymorphonuclear), reduced glucose and elevated protein, with up to 70% patients with cysticercal meningitis having CSF eosinophilia between 2-40% [3].

There are no guidelines for the treatment of acute cysticercal meningitis. Anti-parasitic therapy is recommended for chronic meningitis [10]. Albendazole is the antiparasitic drug of choice. Associated seizures can be readily controlled using standard anticonvulsants [1]. Steroids may decrease the duration of headache in adults with eosinophilic meningitis [5].

The prognosis of eosinophilic meningitis is good; 70% of patients improve sufficiently to leave the hospital in 1–2 weeks, presence of motor deficit and coma can worsen the prognosis [11]. Mortality associated with eosinophilic meningitis is < 1% [5].

**TEACHING POINTS**

Cerebral cysticercal infestations are usually seen as inflammatory granulomas of different stages. The differential diagnosis of cysticercal meningoencephalitis should always be considered in case of CSF eosinophilia even in the absence of typical inflammatory granulomatous lesions.

**ACKNOWLEDGMENTS**

Authors acknowledge the immense help received from the scholars whose articles are cited and included in references of this manuscript. The authors are also grateful to authors/editors/publishers of all those articles, journals and books from where the literature for this article has been reviewed and discussed.

**Figure 1**

A 6 year old boy with cysticercal eosinophilic meningoencephalitis. Axial T2 weighted MR images [Fig. 1a-d] are showing multiple fluffy nodular hyperintensities, involving the bilateral frontal lobes (thin arrows), left parietal lobe (solid white arrow), left centrum semiovale (solid black arrow) and pons in left paramedian plane (arrowhead). (Protocol: Magnet strength - 1 Tesla, TR- 4000, TE - 99, slice thickness – 5 mm, FOV- 187*230). Axial FLAIR (1e-h) images are demonstrating similar findings. (Protocol: Magnet strength - 1 Tesla, TR - 9000, TE - 112, slice thickness – 5 mm, FOV- 187*230).

**Figure 2**

A 6 year old boy with cysticercal eosinophilic meningoencephalitis. Axial DWI (2a-b) are showing hyperintense deep white-matter lesions (solid black arrows) with corresponding low signal intensity (solid white arrows) on the axial ADC map (2c-d), reflecting restricted diffusion. (Protocol: Magnet strength – 1 Tesla, TR- 3000, TE - 123, FOV - 226; b value - 900/180).

**Figure 3**

A 6 year old boy with cysticercal eosinophilic meningoencephalitis. Axial T1 weighted (3a) MR image showing relatively low signal intensity, involving the left corona radiata (solid white arrow). Post Gadolinium (5 ml) contrast im-
ages (3b) demonstrating focal enhancement of genu of corpus callosum (solid black arrow) with subtle enhancement of the meninges (arrowhead). (Protocol: Magnet strength - 1 Tesla, TR - 500, TE - 14, slice thickness – 5 mm, FOV - 187*230).
