ABSTRACT

Introduction:
Nodular fasciitis is a rapidly growing benign, self-limiting, reactive lesion, which due to clinical findings and pathologic appearance can be mistaken for a soft tissue sarcoma. Although nodular fasciitis can occur virtually anywhere in the body, it is commonly found in the volar aspect of the forearm, next in frequency is the chest wall and back, followed by the neck and head. This disorder is extremely rare in the hand. A large series of nodular fasciitis showed only 0%–2% of occurrences in the hand.

Case report:
A 35 year old male patient presented with complaints of swelling in the left palm since 6 weeks. Swelling was initially of the size of 1x1 cm and had progressed to the current size of 3x2 cm and was associated with pain. There was no history of any trauma or similar complaints in the past. On physical examination, a painful mass measuring 3x2 cm in diameter was observed in the left palm below the index and the middle fingers. The swelling was non-mobile, firm in consistency and non-tender upon palpation with a smooth surface and clear margins. Excision was done and specimen was sent for histo-pathological examination. Histo-pathological report showed features of Nodular Fasciitis. Post-operative period was uneventful.

Conclusion:
Nodular fasciitis is a self-limiting benign reactive fibroblastic growth and often mistaken for malignant neoplasm with its features of rapid growth and histological appearance. This is a rare benign condition for which treatment is limited to surgical excision. This is generally curative and relapses are rare.

KEYWORDS
Nodular fasciitis, Pseudosarcomatous fasciitis, Proliferative fasciitis, Parosteal fasciitis.

INTRODUCTION:
Nodular fasciitis is a rapidly growing benign, self-limiting, reactive lesion, which due to clinical findings and pathologic appearance can be mistaken for a soft tissue sarcoma. This lesion is commonly found in the forearm and is extremely rare in the hand. The precise cause of nodular fasciitis is unknown, but despite a benign clinical behavior injury or infection is possible.

CASE REPORT:
A 35 year old male patient presented with complaints of swelling in the left palm since 6 weeks. Swelling was initially of the size of 1x1 cm and had progressed to the current size of 3x2 cm and was associated with pain. There was no history of any trauma or similar swellings in the past.

On physical examination, a non-tender swelling measuring 3x2 cm in diameter was observed in the left palm below the index and the middle fingers. The swelling was immobile, firm in consistency with a smooth surface and clear margins. Clinical diagnosis of dermoid cyst was entertained.

Fig A and B – Swelling present in the palmar surface of left hand

Fine needle aspiration cytology of the swelling was done and report was suggestive of dermoid cyst.

Excision was done under wrist block and specimen was sent for histo-pathological examination.

During the procedure – EXCISION - C to F

Fig G – Excised Specimen

Histo-pathological report showed features of Nodular Fasciitis. Post-operative period was uneventful.
Intramuscular lesions appear mildly homogeneous and including the contrast enhancement pattern, vary. On MRI, literature descriptions of the signal intensity of the condition, other locations.

The features of nodular fasciitis on MR imaging are non-specific. The macroscopic appearance of nodular fasciitis is solitary round to oval nodules, well circumscribed and usually measuring less than 2 cm in diameter. Only 8% are larger than 4 cm. It is often initially misdiagnosed as sarcoma because of its rapidly growing nature of 1 month or less in duration. The etiology of nodular fasciitis remains unclear, but it is considered to be a self-limiting reactive lesion. Bernstein and Lattes described a recognized history of trauma in 5 of 134 cases. Although the number of patients with trauma was low, they described the possibility of minor trauma causing this reactive disorder. Nodular fasciitis of the hand seems to have a close association with trauma compared to other locations.

The lesion may be highly cellular. Although mitotic figures are fairly common, atypical mitoses are almost never seen. Five important histologic features of nodular fasciitis which aid in diagnosis include spindle-shaped fibroblasts, clefts separating the fibroblasts, extravasated erythrocytes, interstitial mucoid material and a loosely textured “feathery” pattern of the mucopolysaccharide ground substance. Immunostains for vimentin and alpha-SMA are usually positive, but desmin, cytokeratin and S-100 are typically negative. Because of common misdiagnosis, incisional or excisional biopsy is usually required for a definitive diagnosis. Montgomery and Meis verified that correct tissue diagnosis of nodular fasciitis was made in fewer than 50% of cases submitted to the Armed Forces Institute of Pathology.

Most lesions are effectively treated by local excision, as reflected by a recurrence rate of 1% to 2%. Recurrence soon after excision has been associated with incomplete excision of the lesion. The current report documents a rare case of nodular fasciitis in the hand. Sufficient knowledge and awareness of this lesion is usually required for the proper management of the case.

REFERENCES:
14. Montgomery EA, Meis JM. Nodular fasciitis. Its morphologic spectrum and hyperintense to skeletal muscle on T1-weighted spin-echo images; whereas T2-weighted spin-echo images, the lesions are relatively homogeneous with hyperintense signal to subcutaneous fat.

Subcutaneous lesions, typically more fibrous than intramuscular lesions, are markedly hypointense to skeletal muscle on all spin-echo sequences and appear homogeneous in texture. High cellularity and micro-vessel density may directly influence the early enhancement after intravenous gadolinium injection and compact cellularity with a prominent capillary network. A myxoid pattern may be responsible for the enhancement on MRI.

Kessels et al. reported that nodular fasciitis was detected by positron emission tomography with 18-F-fluorodeoxyglucose (18-FDG-PET). However when thallium-201 scintigraphy or 18-FDG-PET shows a high uptake similar to sarcoma, nodular fasciitis should be included in the differential diagnosis. Histologically, the lesion is composed of regular spindle-shaped fibroblasts or myofibroblastslacking nuclear hyperchromasia and pleomorphism.

Plaza et al. reported that nodular fasciitis remained a difficult diagnosis by fine-needle aspiration cytology (FNAC), particularly when it occurred in locations such as the hand. Careful histological examination is important to avoid radical surgery. We recommend excisional or incisional biopsy, and a permanent histological section, including immune-histochemical study to confirm the diagnosis.

Most lesions are effectively treated by local excision, as reflected by a recurrence rate of 1% to 2%. Recurrence soon after excision has been associated with incomplete excision of the lesion. The current report documents a rare case of nodular fasciitis in the hand. Sufficient knowledge and awareness of this lesion is usually required for the proper management of the case.

The lesion was followed up for a period of 6 months. There were no signs of recurrence.

DISCUSSION:
Nodular fasciitis is a benign reactive lesion first reported by Konwaler et al. in 1955 as a subcutaneous pseudosarcomatous fibromatosis. It is a rapidly growing mass occurring in all age groups but most often in young adults between 20 and 40 years of age, but with no racial or gender predilection. It is usually subcutaneous, although occasional cases involve muscle and fascia. In about 10%–50% of patients there is associated pain or tenderness. Although nodular fasciitis can occur virtually anywhere in the body, it is commonly found in the volar aspect of the forearm, next in frequency is the chest wall and back, followed by the neck and head. This disorder is less common in the hand. A large series of nodular fasciitis showed only 1%–2% of occurrences in the hand. Since Brimhall et al. first made a detailed case report of nodular fasciitis of the hand in 1989, only 14 cases (including the current case) have been reported in the English literature.

The patient was followed up for a period of 6 months. There were no signs of recurrence.
